Abstract

Banking crises are rare events that break out in the midst of credit intensive booms and bring about particularly deep and long–lasting recessions. This paper attempts to explain these phenomena within a textbook DSGE model that features a non–trivial banking sector. In the model, banks are heterogeneous with respect to their intermediation skills, which gives rise to an interbank market. Moral hazard and asymmetric information in this market may lead to sudden interbank market freezes, banking crises, credit crunches and, ultimately, severe recessions. The model can potentially generate various types of banking crises. But the typical crisis breaks out endogenously, during a credit boom generated by a sequence of small positive supply shocks; it does not result from a large negative exogenous shock. Simulations of a calibrated version of the model indicate that it can mimic the main dynamic patterns of banking crises.

1 Introduction

Recent empirical research on banking crises has highlighted the existence of similar patterns across diverse episodes. Banking crises are rare events. They come along recessions that are deeper and last longer than other recessions. And, more importantly for the purpose of this paper, banking crises follow credit intensive booms; they are “credit booms gone wrong”. In the recent macro-economic literature, banking crises mostly result from the propagation and the amplification of random adverse financial shocks. Rare, large enough, adverse financial shocks can account for the first two properties (see e.g. Gertler and Kiyotaki, 2009). However, by implying that banking crises may break out at any time in the business cycle, they do not seem in line with the fact that the occurrence of a banking crisis is closely linked to credit conditions (Gorton, 2010, 2012). The third stylized fact therefore calls for an alternative approach.

In this paper, banking crises result from the procyclicality of bank balance sheets that emanates from interbank market funding. During expansions, bank market funding and credit supply increase, pushing down the rates of return on corporate and interbank loans. The lower rates aggravate agency problems in the interbank market, which lead to a reduction in market funding and contractions. The larger the credit boom relative to the possibilities for productive use of loans, the larger the fall in interest rates, and the higher the probability of a bank run in —and therefore of a disastrous freeze of— the interbank market. As in Shin (2008) and Hahm et al. (2011), the behavior of banks (credit in our case) during good times sows the seeds of the next banking crisis.

In our model, banks are heterogeneous in terms of —non-publicly observed— intermediation efficiency. They finance their activities with funds obtained from depositors/shareholders or raised in the interbank market. There exists the usual agency problem in this market as borrowing banks can always divert some of the funds into low return assets that cannot be recovered by the lending banks. The incentives for diversion are stronger for less productive banks and depend on the level of interest rates in the economy. The lower the return on corporate loans, the greater the incentive to engage in fund diversion and hence the greater counter-party risk in the interbank market. The typical run of events leading to a banking crisis is as follows. A sequence of favorable, non permanent, supply shocks hits the economy. The resulting increase in productivity leads to an expansion of credit. The more efficient

---

1 See Schularick and Taylor (2012), Borio and Drehmann (2009); the notion that banking crises are endogenous and follow prosperous times is also present in Minsky (1977).

2 Our representation of banking crises as market-based bank runs is consistent with what happened during the 2007–8 financial crisis (see Uhlig, 2010). Shin (2010, Chap. 8), for example, depicts the demise of Northern Rock—a UK bank—in 2007 as primarily originating from the sudden freeze of the short-term funding market, what he refers to as a “modern bank run”. A traditional, deposit-based, run on the bank took place as well, but it did so one month later, accounted for only 10% of the bank’s fall in total funding, and rapidly stopped because, following the news of the run, the UK authorities pledged 100% deposit guarantees.
banks expand their corporate loan operations by drawing funds from the less efficient banks and the size of the banking sector as a whole increases. The economy booms. But as supply shocks run their course, the probability of imminent reversion to average productivity increases. This slows down corporate demand for loans while at the same time inducing households to accumulate savings in order to smooth consumption. As this saving glut develops, interest rates go down. The rate of return on interbank loans declines making the less efficient banks more prone to borrow and divert those funds. The identity of these banks being unknown to lenders, counter–party risk in the interbank market increases, interbank loans decline, and market finance recedes. The stronger the credit expansion during the booming times, the larger the decline in interest rates and the sharper the agency problem in the interbank market. We show that there is a threshold value of interest rates below which the interbank market freezes, corporate credit collapses and the economy tanks. This threshold can be alternatively expressed in terms of the level of banking assets relative to the level of productivity (output) in the economy, which we call the absorption capacity of the banking sector. Excessive credit creation shifts the economy beyond its absorption capacity, triggering a banking crisis.

There have been many attempts to analyze banking crises within otherwise standard macroeconomic models. For instance, Bernanke et al. (1999), Jermann and Quadrini (2012), Christiano et al. (2013), Gertler and Karadi (2011) show how adverse wealth or financial shocks can be amplified by financial market frictions and generate deep and long lasting recessions. We depart from these approaches in that we do not analyze a linearized version of our model but instead characterize the full equilibrium dynamics, inclusive of important and critical non-linearities such as the freezing of interbank markets. This is an important difference because, near the steady state, our model features the traditional financial accelerator that the previous models possess. But away from it (and the large departures from the steady state are the endogenous outcome of a boom-bust endogenous cycle, rather than a big shock) it gives rise to banking crises. Crises are rare but generate particularly large output losses and inefficiencies due to the presence of pecuniary externalities. In this respect, our work relates to the sudden stops literature and the influential work by Mendoza and Smith (2005), Mendoza (2010), Bianchi (2011), Bianchi and Mendoza (2010), which also feature non–linearities and externalities. One important difference with sudden stops models is that they typically consider small open economies, in which the interest rate is exogenous, whereas in our case the endogenous dynamics of interest rates plays a central role. Furthermore, in these models, financial frictions affect non–financial firms and entail excess credit demand (i.e., “over–borrowing”). In our case, they affect the banking sector and generate excess credit supply. Our model is also close to Brunnermeier and Sannikov (2012) and He and Krishnamurthy (2012) in that it features powerful non–linear amplification mechanisms. The novelty of our approach is that a banking crisis does not necessarily result from an adverse exogenous
shock, and the size and sign of the shock play a less important role. When the size of the banking sector is large with respect to aggregate output, it is even possible that crises break out endogenously, in the absence of shocks. Another noticeable feature is that we abstract from financial shocks, which are not necessary in the model to generate banking crises. Finally, our model departs from the existing literature in that banking crises are not due to occasionally binding collateral constraints. They are due to occasional financial market runs, which we find to be particularly disruptive and more costly in terms of welfare than the usual collateral constraints. The welfare losses due to the externalities are for example three times as large in our model as in Bianchi (2011).

We calibrate the model on post–WWII US data and the financial cycles in fourteen OECD countries (1870-2008), and assess its quantitative properties. Most of the time bank assets remain below the threshold for banking crises and the model behaves like a standard financial accelerator model. But once in a while —on average every forty years— there is a banking crisis. The model can potentially generate a variety of banking crises but the simulations indicate that the typical crisis breaks out endogenously, during a credit boom generated by a sequence of small positive supply shocks. Thus, as in the data, banking crises are closely linked to credit conditions; they also bring about more severe and longer–lasting recessions.

The paper proceeds as follows. Section 2 documents stylized facts about financial recessions in 14 OECD countries for the period 1870–2008. Section 3 describes our theoretical framework, the micro-foundations of interbank market freezes and the dynamic implications of such events. In Section 4 we solve a calibrated version of the model and describe the typical dynamics to banking crises. Section 5 discusses the ability of the model to account for the stylized facts and the sensitivity of the results to alternative parameterizations. Section 6 evaluates the various welfare costs associated with the existence of financial frictions. A last section concludes.

2 Facts on Financial Recessions

The recent empirical literature has put forward a set of facts that seem to indicate that financial recessions — recessions that are concomitant with banking crises — are special events that significantly differ from other types of recessions. Reinhart and Rogoff (2009) report that banking crises have historically been followed by profound declines in output and employment, with output falling by about 9% from peak to trough and the duration of the downturn averaging roughly two years. This is much more than during ordinary

Angeloni and Faia (2013) also propose a model with bank runs, but their runs are idiosyncratic and frequent, while ours are systemic and rare. Like us, Gertler and Kiyotaki (2013) also develop a model where bank runs induce regime switches. One important difference is that in their model bank runs are deposit–based and unanticipated, while in ours they are market–based and agents are fully rational: they perfectly know and take into account the probability that runs will occur in the future.
recessions, possibly because financial recessions come along with a credit crunch that amplifies the downturn, as Claessens et al. (2008, 2011) show. Mendoza and Terrones (2012) and Schularick and Taylor (2012), among others, also provide evidence that banking crises follow credit booms. For instance, Schularick and Taylor (2012) show that high credit growth is a robust predictor of future banking crises in the case of advanced economies. The predictive power of credit may not necessarily reflect a causal relationship, as credit is strongly correlated with other financial phenomena that have also been found to precede banking crises like asset price bubbles or large capital inflows (Kaminski and Reinhart, 1999; Reinhart and Rogoff, 2008, 2009). However, these other factors seem to be more relevant for emerging market economies than for advanced countries (Reinhart and Reinhart, 2009) where credit remains a strong predictor even once past current account deficits, asset prices, or GDP growth are controlled for (Jordà, Schularick and Taylor, 2011a,b; Schularick and Taylor, 2012). The different evolution of the GDP and credit gaps around financial and non–financial recessions shown in Figure 1 illustrates these facts, which we document in more detail below using the data compiled by Schularick and Taylor (2012) and Jordà, Schularick and Taylor (2011a,b).

Figure 1: Dynamics of GDP and credit gaps around recessions

![Figure 1: Dynamics of GDP and credit gaps around recessions](image)

Note: Average dynamics of the Hodrick-Prescott ($\lambda = 6.25$) cyclical component of (log) output and credit 6 years before and after the start of a business cycle (period 0) with and without a banking crisis. The data are from Schularick and Taylor (2012) and Jordà, Schularick and Taylor (2011a,b).

The data set comprises yearly observations from 1870 to 2008 in 14 developed countries for real GDP per capita, total domestic currency loans of banks and banking institutions to non–financial companies and households, the dates of business cycle peaks, and the dates of banking crises. Following Reinhart and Rogoff (2008) and Laeven and Valencia (2008), a banking crisis in the data refers to an event during which the financial sector experiences bank runs, sharp increases in default rates accompanied by large capital losses that result in public intervention, bankruptcy, or the forced merger of major financial institutions. As is common in the literature, we define a recession as a financial recession when a banking crisis breaks out between the peak year that precedes it and trough year that ends it (see Jordà, Schularick and Taylor, 2011b). Excluding war times, the data set includes 78 banking crises for a total of 1,736 country/year observations, and includes 161 complete business cycles —
i.e. periods between two business cycle peaks. We use these data and describe three key facts on financial recessions.

Note: Δp,t,x (resp. Δp,t+2,x, Δp,−2,x) denotes the percentage change of variable x from peak to trough (resp. from peak to peak+2 years, and peak-2 years to peak), where x denotes either GDP per capita (y) or the Hodrick Prescott (λ = 6.25) cyclical component of credit per capita (kHP). A severe (mild) recession is a recession associated with a peak-to-trough output loss in the top (bottom) three deciles of the distribution. All statistics are averages over the full sample of 1,736 country/year observations, except the peak–to–trough statistics, which are averages over the 161 complete business cycles only (1,333 country/year observations). *,**: the difference between financial (resp. severe) recessions and other (resp. mild) recessions is statistically significant at the 10%, 1% thresholds.

Fact #1: Financial recessions are rare events. Among the 196 recessions identified in the sample, 41 are associated with a banking crisis, which corresponds to an average probability of a financial recession of 2.36%. Hence, financial recessions are rare events; by comparison, the probability of other types of recession is 8.93% (see Table 1).

Fact #2: Financial recessions are deeper and last longer than other recessions. In our sample, financial recessions last on average 2.32 years, about eight months longer than other recessions. During these episodes real GDP per capita falls almost twice as much, from peak to trough, than during other recessions (6.84% against 3.75%). These differences are statistically significant at the 1% level and, importantly, they are unlikely to be due to severe recessions causing non–performing loans, bank capital losses, and ultimately banking crises. Indeed, should it be the case, we would observe that banking crises tend to break out after the recessions start, once bank capital losses have accumulated. In our sample, we find the opposite: in 32 out of 41 financial recessions the banking crisis breaks out either in the year before or in the very first year of the recession. Table 1 also shows that the credit gap falls by more during financial recessions (-3.94%) than during other recessions (-2.09%). We find similar differences when we look at the level of credit (not reported): during financial
recessions credit falls by 1.24%, which is unusual as during recessions credit growth usually
decelerates but remains positive (see, e.g., Claessens et al., 2008). Altogether, these results
suggest not only that financial recessions are accompanied with a credit crunch but also that,
in the case of financial recessions, it is the severity of the recession that results from financial
distress —and not the other way around.

**Fact #3: Financial recessions follow credit booms.** Banking crises, and *a fortiori*
financial recessions, do not hit at random (Gorton, 1988) but instead break out in the midst
of a credit boom (Schularick and Taylor, 2012). The bottom of Table 1 illustrates this point.
It shows that credit grows significantly faster before financial recessions than before other
recessions (4.56% against 0.01%). Credit is also 3.34% above its trend in the peak year
that precedes a financial recession, whereas it is only 0.62% above trend in the case of other
recessions. All these differences are statistically significant at the 1% threshold. In contrast,
there is no such difference between mild and severe recessions (last two columns of Table 1).
In other words, only financial recessions are associated with credit booms, which suggests
that a country’s recent history of credit growth helps predict a financial recession. To test

Note: All models include country fixed effects and the lagged growth rates of real credit and real GDP per
per capita (the coefficients are reported in Section D.1 of the companion technical appendix). First column:
replication of Schularick and Taylor (2012, page 1052, Table 6, model (15)); the dependent variable is a
dummy equal to one in the country/year where a banking crisis breaks out. Other models: the dependent variable
is a dummy equal to one in the country/year where a recession starts. Last column: as in Table 1
a severe recession is a recession associated with a peak-to-trough growth rate of real GDP per capita in the
bottom three deciles of the distribution; Denmark and Germany are excluded because of the fixed effects.
Standard errors in parentheses. *: Significant at the 1% threshold.

this idea formally we build upon Schularick and Taylor (2012) and estimate the probability
that a recession starts in a given country in a given year as a function of the country’s lagged
real credit growth, and check whether credit indeed matters. To control for potential omitted
variables and reverse causality we also include five lags of real GDP growth in the model.
The results are reported in Table 2. For comparison, the first column replicates Schularick
and Taylor’s logit model for banking crises; the other three columns correspond to our model
for all types of recessions, as well as for financial and severe recessions separately. The results
essentially confirm the statistics in Table 1. The sum of the coefficients on lagged credit
growth is positive and significant in the case of financial recessions only. Credit helps predict financial recessions, but it is of no use to predict other types of recessions, be they severe or not. We conclude that financial recessions are indeed special, that they are credit booms gone bust. This result is important because it establishes the role of credit as an endogenous source of financial instability —and not merely as an amplifier of exogenous shocks.

3 The Model

We consider a closed economy populated with one representative risk averse household, one representative risk neutral competitive firm, and a mass one of heterogeneous, risk neutral, and competitive banks.

3.1 The Representative Firm

The representative firm lives for one period. It produces a homogeneous good, that can be either consumed or invested, by means of capital, $k_t$, and labor, $h_t$, according to a constant returns to scale technology represented by a production function $z_t F(k_t, h_t)$ that satisfies standard Inada conditions. The level of total factor productivity (TFP), $z_t$, is assumed to follow an exogenous AR(1) process of the form

$$\log z_t = \rho z \log z_{t-1} + \varepsilon_t,$$

where $|\rho_z| < 1$ and $\varepsilon_t$ is an normally distributed innovation with zero mean and standard deviation $\sigma_z$. Variations in productivity are the only source of uncertainty and $\varepsilon_t$ is realized at the beginning of period $t$, before the firm decides on its production plan. Capital, $k_t$, depreciates at rate $\delta \in (0, 1)$. The firm is born with no resources and must borrow $k_t$ from the banks at a gross corporate loan rate $R_t$ at the beginning of the period. The corporate loan is repaid at the end of the period. The firm also rents labor services from the household at rate $w_t$. The production plan is decided so as to maximize profit

$$\pi_t = z_t F(k_t, h_t) + (1 - \delta)k_t - R_t k_t - w_t h_t.$$  \hspace{1cm} (1)

3.2 The Representative Household

The economy is populated by an infinitely lived representative household that has preferences over consumption, $c_t$, represented by the utility function:

$$\mathbb{E}_t \sum_{\tau=0}^{\infty} \beta^\tau u(c_{t+\tau}),$$

where $u(c_t)$ satisfies the usual regularity conditions (i.e., $u'(c) > 0$, $u''(c) < 0$, $u'(0) = \infty$, $u'(\infty) = 0$), $\beta \in (0, 1)$ is the psychological discount factor, and $\mathbb{E}_t (\cdot)$ denotes the expectation.
operator which is taken over \( \{e_{t+\tau+1}\}_{\tau=0}^{+\infty} \). For expositional convenience, we assume that the household supplies inelastically one unit of labor; we will relax this assumption in the quantitative analysis of the model (see Section 4.1). The household enters period \( t \) with assets \( a_t \), which yield a state contingent gross return \( r_t \). There is no friction between the household and the banks, which implies that banks’ funding structure and leverage will be indeterminate. Hence, bank leverage will not be a source of financial fragility in our model.

Since the composition of \( a_t \) is indeterminate, \( a_t \) can be thought of either as bank deposit or as bank equity. To ease exposition, we will refer to it as bank deposit, and to \( r_t \) as the gross return on bank deposit. Following the macro–finance literature (e.g. Gertler and Kiyotaki, 2009; Gertler and Karadi, 2011) we assume that there exist frictions between the household and the firm that prevent the household from financing the firm directly. The household earns unit wage \( w_t \) from supplying her labor, receives profits \( \pi_t \) from the firm, and gets a lump–sum transfer \( \chi_t \) that corresponds to banks’ financial intermediation costs (see next section). She therefore decides on her consumption/saving decisions maximizing her utility (2) subject to the budget constraint

\[
c_t + a_{t+1} = r_t a_t + w_t + \pi_t + \chi_t. \tag{3}
\]

3.3 The Banking Sector

The banking sector is at the core of the model and plays a non–trivial role because of two specific features. First, banks are heterogeneous with respect to their intermediation technology — some banks are more efficient than others, which potentially gives rise to an interbank market. Second, the banking sector is subject to both asymmetric information and moral hazard problems, which impair the functioning of the interbank market. Overall, banks engage in two types of activities. They make traditional retail banking operations, which consist in collecting deposit from households and in lending the funds to the firm. Banks also make wholesale banking operations by issuing interbank claims, through which they reallocate assets among themselves — typically from the least efficient to the most efficient banks.

3.3.1 Banks

There is a continuum of one–period, risk–neutral, competitive banks that raise deposits \( a_t \) from the household at the end of period \( t–1 \). The banks that operate in period \( t \) are born at the end of period \( t–1 \) and die at the end of period \( t \). When they are born, banks are

---

4 For an extension with endogenous bank leverage, see Section E.2 of the companion technical appendix.

5 We will assume in a moment that banks are heterogeneous and that their types are private information. The assumption of one–period living banks is made to preserve this asymmetry of information over time. An alternative — but equivalent — approach would be to allow banks to live infinitely and, in order to rule out potential reputation effects, to assume that the types are randomly drawn afresh every period.
all identical and raise the same amount of deposits, \(a_t\). They then draw a random, bank–specific, intermediation skill and become heterogeneous. Let \(p\) denote the bank with skill \(p\), and assume that the \(p\)s are distributed over interval \([0, 1]\) with cumulative distribution \(\mu(p)\), satisfying \(\mu(0) = 0, \mu(1) = 1, \mu'(p) > 0\). Bank \(p\) must pay an intermediation cost \((1 – p)R_t\) per unit of corporate loan at the end of the period, so that the net unit return of the loan is \(pR_t\). These costs are rebated to the household in the form of lump–sum transfers that amount to \(\chi_t\), so that there is no dead–weight loss in the economy. These intermediation costs reflect the prospection, screening, and monitoring costs that banks may face either as loan originators or as loan servicers. Banks also have, as outside option, the possibility to invest funds in their own project. We assume that this project yields a constant gross return \(\gamma\) per unit of good invested and is worth more than just letting the good depreciate (i.e., \(\gamma \geq 1 – \delta\)). To fix ideas, we will refer to this outside option as storage.

Bank heterogeneity gives rise to an intra–periodic interbank market, where the least efficient banks lend to the most efficient ones at gross rate \(\rho_t\). This rate is the same for all borrowers; otherwise the borrowers that promise the lowest returns would not attract any lender. Moreover, in equilibrium \(\rho_t\) must be strictly lower than \(R_t\); otherwise no bank would lend to the firm and the Inada conditions on the firm’s production function would imply that \(R_t\) is infinite. Similarly, \(\rho_t\) must be bigger than \(\gamma\); otherwise no bank would lend to other banks. It follows that, in an equilibrium, storage is an inefficient technology as it must be the case that \(\gamma < R_t\). Banks take \(\rho_t\) and \(R_t\) as given. Given these rates, bank \(p\) decides whether, and how much, it borrows or lends. By convention, we will call the banks that supply funds on the interbank market the “lenders” and those that borrow the “borrowers”. Let \(\phi_t\) be the — endogenous and publicly observable — amount borrowed on the interbank market per unit of deposit by a borrower \(p\), with \(\phi_t \geq 0\). Since \(\phi_t\) is the ratio of market funding to traditional funding, we will refer to it as banks’ “market funding ratio”. Note that one cannot interpret \(\phi_t\) as a leverage ratio because (i) market funding is only one of the two components of bank liabilities — the other one being deposits — and (ii) the bank deposit structure is indeterminate. Let \(r_t(p)\) be bank \(p\)‘s gross return on deposit, with

\[
r_t(p) \equiv \max \{ pR_t (1 + \phi_t) – \rho_t \phi_t, \rho_t \} .
\]

It is equal to \(pR_t (1 + \phi_t) – \rho_t \phi_t\) when bank \(p\) borrows \(\phi_t a_t\) from other banks at cost \(\rho_t\) and lends \((1 + \phi_t) a_t\) to the firm for return \(pR_t\). It is equal to \(\rho_t\) when, instead, bank \(p\) decides to lend.\footnote{The way we model these costs is not critical, in the sense that we would find qualitatively similar results (i) if they were dead–weights (see Boissay et al., 2013), (ii) if they were paid at the beginning of the period, (iii) if \(p\) were the fraction of the loan that the firm repays to bank \(p\), or (iv) if \(p\) were the probability that the firm reimburses bank \(p\) (see Boissay, 2011). We do not introduce these features in the model so as to stay the closest possible to the textbook neoclassical model, where all deposit are channeled to firms and firms do not default.}
lend the deposit it collected to other banks. Bank $p$ chooses to be a borrower when

$$pR_t (1 + \phi_t) - \rho_t \phi_t \geq \rho_t \iff p \geq \overline{p}_t \equiv \frac{\rho_t}{R_t}.$$  \textbf{(PC)}

Inequality \textbf{(PC)} is the participation constraint of bank $p$ to the interbank market as borrower, rather than as lender, and pins down the type of the marginal bank $\overline{p}_t$ that is indifferent between the two options. Banks with $p < \overline{p}_t$ delegate financial intermediation to more efficient banks with $p \geq \overline{p}_t$. In a frictionless world, all banks with $p < 1$ would lend to the most efficient bank, so that $\overline{p}_t = 1$. This bank would then have an infinite market funding ratio ($\phi_t \to +\infty$) and the economy would reach the First Best allocation. In this model, two frictions on the interbank market — moral hazard and asymmetric information — prevent the economy from reaching the First Best allocation.

\textbf{Moral Hazard:} We assume that the proceeds of the storage technology are not traceable and cannot be seized by creditors. As a consequence, interbank loan contracts are not enforceable, banks may renege on paying their interbank debt and walk away with the funds. A bank that walks away with $(1 + \phi_t)\alpha_t$ can invest in the storage technology and gets $\gamma (1 + \theta \phi_t)\alpha_t$ as pay-off, with $\theta \in [0,1]$. Following the current practice (e.g. Hart, 1995, Burkart and Ellingsen, 2004), we refer to such an opportunistic behavior as “diversion”. From a corporate finance literature viewpoint (e.g. Tirole, 2006), this is a standard moral hazard problem: (i) the gain from diversion increases with $\phi_t$, (ii) the opportunity cost of diversion increases with bank efficiency $p$ and (iii) with the corporate loan rate $R_t$. Features (i) and (ii) imply that efficient banks with “skin in the game” are less inclined to walk away than highly leveraged and inefficient banks. Feature (iii) is similar to feature (ii), but in the “time–series” (as opposed to “cross–sectional”) dimension; it implies that banks are more inclined to walk away when the return on corporate loans is low. This latter feature captures recent empirical evidence that banks tend to take more risks when interest rates are low (Maddaloni and Peydro, 2011).

\textbf{Asymmetric Information:} The $p$s are privately known so that lenders can neither observe \textit{ex ante} nor verify \textit{ex post} the borrowers’ skills, and therefore ignore the borrowers’ private incentives to divert funds. As a result, the loan contracts signed on the interbank market are the same for all banks. Neither $\phi_t$ nor $\rho_t$ depends on $p\footnote{To see this, consider a menu of debt contracts $\{\rho_t(\overline{p}), \phi_t(\overline{p})\}_{\overline{p} \in [0,1]}$ intended for the borrowers of types $\overline{p}$s, and notice that lenders’ arbitrage across these contracts requires that $\rho_t(\overline{p}) = \rho_t$, $\forall \overline{p} \in [0,1]$. It is easy to see that such a menu of contracts cannot be revealing because any borrower $p$ (i.e. with $pR_t > \rho_t$) claiming being of type $\overline{p}$ would make profit $r_t (\overline{p} | p) = pR_t + (pR_t - \rho_t) \phi_t (\overline{p})$ and pick the contract with the highest $\phi_t (\overline{p})$, independent of its type. It is equally easy to see that there is no revealing menu of equity contracts either. Indeed, consider a menu of equity contracts $\{r_t(\overline{p}), \phi_t(\overline{p})\}_{\overline{p} \in [0,1]}$; where $r_t(\overline{p})$ would be the share of retained earnings. Then the net profit of bank $p$ would be $r_t(\overline{p}) (1 + \phi_t(\overline{p})) pR_t$ and, in equilibrium, this bank would pick the contract that yields the highest $r_t(\overline{p}) (1 + \phi_t(\overline{p}))$, independently of its own $p.$}. By limiting the borrowing capacity of the most efficient bank ($p = 1$), moral hazard will give less efficient banks room to borrow; hence a positive wedge between $R_t$ and $r_t$. Moral
hazard is not enough to generate market freezes though. Uncertainty about the quality—and therefore some selection—of borrowers is also needed. Hence, both moral hazard and information asymmetry will be necessary to generate banking crises in the model.

Lenders want to deter borrowers from diverting. They can do so by limiting the quantity of funds that borrowers can borrow so that even the most inefficient banks with \( p < \bar{p}_t \)—those that should be lending—have no interest in demanding a loan and diverting it:

\[
\gamma (1 + \theta \phi_t) \leq \rho_t. \tag{IC}
\]

This incentive compatibility constraint sets a limit to \( \phi_t \), which can therefore also be interpreted as lenders’ funding tolerance, *i.e.*) the market funding ratio above which a bank refuses to lend or, in Holmström and Tirole’s language, the borrower’s pledgeable income.\(^8\) The program of bank \( p \geq \bar{p}_t \) thus consists in maximizing its return on equity \( r_t(p) \) (see relation (4)) with respect to \( \phi_t \) subject to constraint (IC). Proposition 1 follows.\(^9\)

**Proposition 1 (Optimal Market Funding Ratio)** The IC constraint binds at the optimum of the borrowing bank \( p \), which thus exhausts its borrowing capacity: \( \phi_t = \frac{\rho_t - \gamma}{\gamma \theta} \).

The positive relationship between \( \phi_t \) and \( \rho_t \) is a critical feature of the model. When \( \rho_t \) decreases, the net present value of corporate loans rises and the least efficient banks enter the demand side of the market. Since the private incentives to divert are higher for those banks, lenders tolerate a lower market funding ratio (\( \phi_t \) goes down). In the limit case when \( \rho_t = \gamma \), there is no demand for interbank loan because no borrower can commit to repay. The market funding ratio \( \phi_t \) and the type of the marginal bank \( \bar{p}_t \) fully describe banks’ optimal decisions.

### 3.3.2 Interbank Market

The equilibrium of the interbank market is characterized by the gross return \( \rho_t \) that clears the market. We look for an equilibrium where \( \rho_t > \gamma \) so that \( \phi_t > 0 \) and trade takes place. Since a mass \( \mu (\bar{p}_t) \) of banks lend \( a_t \), the aggregate supply of funds is equal to \( \mu (\bar{p}_t) a_t \). Likewise, a mass \( 1 - \mu (\bar{p}_t) \) of banks borrow \( \phi_t a_t \), and aggregate demand is equal to \( (1 - \mu (\bar{p}_t)) \phi_t a_t \).

The market clears when (using relations (PC) and Proposition 1):

\[
\frac{a_t \mu \left( \frac{\rho_t}{R_t} \right)}{\left( 1 - \mu \left( \frac{\rho_t}{R_t} \right) \right)} \left( \frac{\rho_t - \gamma}{\gamma \theta} \right) \left( \frac{\rho_t - \gamma}{\gamma \theta} \right) \iff R_t = \Psi(\rho_t) \equiv \frac{\rho_t}{\mu - 1} \left( \frac{\rho_t - \gamma}{\rho_t - \gamma \left( 1 - \theta \right)} \right). \tag{5}
\]

\(^8\)One could indeed recast the moral hazard problem into a setup *à la* Holmström and Tirole (1997), whereby borrowers may misuse the funds and enjoy private benefits at the expense of their creditors. *Stricto sensu*, the pledgeable income is the highest income that can be pledged without jeopardizing the borrower’s incentives, *i.e.*) \( \rho_t (\rho_t - \gamma) a_t / \gamma \theta \).

\(^9\)The proofs of propositions are reported in Appendix B.
Aggregate supply increases monotonically with $\rho$, whereas aggregate demand is driven by two opposite forces. On the one hand, aggregate demand decreases with the interbank loan rate because fewer borrowers demand funds when the cost of funds increases; this is the “extensive margin” effect. On the other hand, a rise in $\rho$ also exerts a positive effect on aggregate demand because each borrower is then able to borrow more; this is the “intensive margin” effect. At the aggregate level, this latter effect more than offsets the extensive margin effect when the marginal bank’s externality affects a large mass of borrowers, i.e. when $\rho$ is small enough. It follows that the aggregate demand curve bends backward, increasing with $\rho$ for small values of $\rho$ (see Figure 2). One can check that $\Psi(\rho)$ is strictly convex, goes to infinity as $\rho$ approaches $\gamma$, is greater than $R$ when $\rho$ approaches $R$, and reaches a minimum for some value $\rho = \overline{\rho} > \gamma$. Hence there exists a threshold $\overline{R} \equiv \Psi(\overline{\rho})$ for $R$, below which there is no equilibrium with trade, and above which there are two equilibria with trade. This threshold is the minimum corporate loan rate that is necessary for the banks to accept to lend to each other. Figure 2 illustrates this point and depicts the shifts in aggregate supply and demand as $R$ falls from $R_\text{E}$ (equilibrium $E$) to $R_\text{L}$ (equilibrium $A$), with $R_\text{L} < \overline{R} < R_\text{H}$. Following the fall in the corporate loan rate, the supply curve shifts to the right while the demand curve shifts to the left. Given the initial equilibrium rate $\rho = \rho_\text{E}$, demand falls below supply. Market clearing then requires that $\rho$ goes down, which results in more banks demanding funds (extensive margin). But since the banks that switch from the supply to the demand side are less efficient and have a relatively higher private incentive to divert cash, lenders require borrowers to reduce their demand for loan. By construction, this intensive margin effect is the strongest when $R < \overline{R}$. It follows that, ultimately, aggregate demand decreases and excess supply goes further up. This process feeds itself and goes on until the market freezes, in point $A$, where by convention we set $\rho = \gamma$. Interbank market freezes in the model are reminiscent of Mankiw (1986)’s credit market collapses. In Mankiw (1986), changes in the interest rate also alter the composition and the quality of the pool of borrowers. One important difference, though, is that, in our case, banks can be on either side of the loan market and choose which side they stand on. So, following an increase in the interest rate low quality borrowers switch to the supply side and the average quality of the remaining borrowers improves, whereas in a typical adverse selection model, like Mankiw’s, quality would deteriorate. This peculiar borrower selection mechanism explains why low—not high—interest rates are conducive to market freezes. Moreover, since low interest rates may be induced by a—supply–driven—boom in credit, this mechanism will also contribute to explain why banking crises may occur after credit booms (Fact #3).

When $R \geq \overline{R}$ the aggregate supply and demand curves intersect at points $U$ and $E$. In this case it seems reasonable to restrict attention to $E$ and to rule out $U$ as not tâtonnement–stable (see Mas–Colell et al., 1995, Chapter 17.H). At this point net aggregate demand is indeed a decreasing function of $\rho$, and following any small perturbation to $\rho$ a standard
price tâtonnement process would push \( \rho_t \) away from \( \rho_U \). Similar reasoning shows that point \( E \) is a stable equilibrium. Since in this equilibrium trade takes place, we will refer to \( E \) as normal times.

In equilibrium \( A \), in contrast, no trade takes place. Both aggregate loan demand and supply are equal to zero because borrowers have no pledgeable income \((\phi_t = 0)\) and lenders are indifferent between interbank loans and storage. In this case, there exists a cut–off \( \bar{p}_t = \gamma / R_t \) such that banks with \( p < \bar{p}_t \) store, banks with \( p > \bar{p}_t \) are better off lending to the firm, and bank \( \bar{p}_t \) is indifferent. We will refer to such no–trade equilibrium as a banking crisis\(^{10}\) This equilibrium always exists —irrespective of \( R_t \), is stable, and therefore co–exists with \( E \) whenever \( E \) exists. Because it is Pareto–dominated by \( E \), though, we rule it out in this case by assuming that banks always coordinate on \( E \)\(^{11}\)

\(^{10}\)As will be clear later, this situation corresponds to a regime switch, in which the economy experiences a large drop in output. Regime switching can be thought of as a way to endogenize rare exogenous shocks to disaster risk (e.g., see Gourio, 2012) or to generate non–linear dynamics like in catastrophe theories (e.g., see Varian (1979) for an introduction).

\(^{11}\)Two comments are in order. First, note that when \( R_t \geq \bar{R} \) we could possibly generate sunspot equilibria by randomizing between outcomes \( A, U \), and \( E \), with a sunspot variable coordinating the beliefs of the banks. This would neither complicate the numerical resolution of the model nor change in a material way its qualitative properties. But, from a quantitative viewpoint, sunspot equilibria would not be consistent with Fact \( \# 3 \) that banking crises do not hit at random. For a discussion on the selection of the Pareto–dominant equilibrium in games with multiple Pareto–rankable Nash equilibria, see Cooper et al. (1990). Second, also note that rationing equilibria (with excess aggregate supply) are ruled out by bank competition. Indeed, in a rationing equilibrium, some inefficient banks would be rationed; and since these banks only have storage as relevant outside investment opportunity they would always be better off by deviating from the rationing equilibrium
Using relations (4) and (5), we can complete the description of the banking sector and derive the sector’s return on deposit:

$$r_t = \int_0^1 r_t(p) \, d\mu(p) = \begin{cases} R_t \int_{\mathcal{P}_t}^1 p \, d\mu(p) / \left(1 + \mu_{\mathcal{P}_t}\right), & \text{if an equilibrium with trade exists} \\ R_t \left(\frac{\gamma}{R_t} \mu_{\mathcal{P}_t} \left(\frac{\gamma}{R_t}\right) + \int_{\mathcal{P}_t}^1 p \, d\mu(p)\right), & \text{otherwise.} \end{cases} \quad (6)$$

Relation (6) reflects the fact that in normal times the least efficient banks delegate financial intermediation to a mass $1 - \mu_{\mathcal{P}_t}$ of more efficient banks, each of which lending to the firm a multiple $1 + \phi_t = (1 - \mu_{\mathcal{P}_t})^{-1}$ of their initial assets at effective return $pR_t$. In the no-trade equilibrium, in contrast, banks do not delegate intermediation, and a mass $\mu_{\mathcal{P}_t} \left(\gamma / R_t\right)$ of the banks use the storage technology.

### 3.3.3 Aggregate Supply of Corporate Loans

We are now in the position to describe the aggregate supply of corporate loans by the banking sector. The supply of corporate loans depends on whether or not the interbank market functions. When interbank trades are possible, all bank assets are channeled to the firm, so that the supply of corporate loans is $a_t$. When the interbank market is frozen, banks with $p < \gamma / R_t$ use the storage technology and the aggregate supply of corporate loans is $(1 - \mu_{\mathcal{P}_t}) a_t$; denoting this supply by $k_t$, one gets:

$$k_t = \begin{cases} a_t, & \text{if an equilibrium with trade exists} \\ (1 - \mu_{\mathcal{P}_t}) a_t, & \text{otherwise} \end{cases} \quad (7)$$

Even though the use of the storage technology during crisis times is optimal from a private point of view, it is inefficient because the return on storage is less than the marginal return of the firm’s project. It follows that, during crises, banks inefficiently divert assets away from the firm — a phenomenon we will refer to as a credit crunch. Proposition 2 follows.

**Proposition 2 (Interbank Market Freeze and Credit Crunch)** An interbank market freeze is accompanied with a credit crunch.

### 3.4 Decentralized General Equilibrium

A general equilibrium of the economy is defined as follows.

**Definition 1 (Decentralized general equilibrium)** A decentralized general equilibrium is a sequence of prices $\mathcal{P}_t \equiv \{R_{t+i}, r_{t+i}, p_{t+i}, w_{t+i}\}_{i=0}^{\infty}$ and a sequence of quantities $\mathcal{Q}_t \equiv \{a_{t+i}, k_{t+i}\}_{i=0}^{\infty}$, where $\mathcal{P}_t$ and $\mathcal{Q}_t$ are specified by the loan contract. Hence our model differs from the standard Stiglitz and Weiss (1981) adverse selection model with monopolistic banks.
\{c_{t+i}, y_{t+i}, k_{t+i}, h_{t+i}, a_{t+i}\}_{i=0}^{\infty} \text{ such that for a given sequence of prices, } P_t, \text{ the sequence of quantities, } Q_t, \text{ solves the optimization problems of the agents, and for a sequence of quantities, } Q_t, \text{ the sequence of prices, } P_t, \text{ clears the markets. The market clearing conditions in the interbank and credit markets are given by equations (2) and (7); and those of the labor and good markets by } h_t = 1 \text{ and the usual resource constraint } y_t = c_t + i_t.

Since in equilibrium the household supplies one unit of labor, the level of production is \( z_t f(k_t) = z_t F(k_t, 1) \), the marginal productivity of capital is \( z_t f_k(k_t) = z_t \partial F(k_t, 1)/\partial k_t \), and the aggregate demand for capital (and credit) is \( k_t = f_k^{-1}((R_t + \delta - 1)/z_t) \). It follows that the market clearing condition on the corporate loan market takes the form

\[
f^{-1}_k \left( \frac{R_t + \delta - 1}{z_t} \right) = \begin{cases} a_t, & \text{if an equilibrium with trade exists} \quad (a) \\ a_t - \mu \left( \frac{\gamma}{R_t} \right) a_t, & \text{otherwise.} \quad (b) \end{cases}
\]

Relation (8) yields the equilibrium \( R_t \) as a function of the two state variables of the model, \( a_t \) and \( z_t \). It also points to the two–way relationship that exists between the interbank loan market and the retail corporate loan market. We already showed that the way the interbank operates depends on whether or not \( R_t \geq R \). Likewise, whether or not the interbank market operates affects the supply of corporate loans and \( R_t \). The corporate loan market equilibrium must therefore be solved sequentially. We first solve (8) for \( R_t \) assuming that an interbank market equilibrium exists (using (8a)) and check that \( R_t \geq R \). In the negative, the interbank market equilibrium with trade cannot emerge (the interbank market freezes), and banks reduce their supply of loans to the firm. The corporate loan rate, \( R_t \), then solves (8b). Note that in the no–trade equilibrium \( R_t \) may well be above \( R \); for example, it is the case for \( R_t \) in Figure 3. But this rate is irrelevant for the existence of interbank trades because, in the absence of coordination failures, the only rate that matters in this respect is the one that would prevail in the equilibrium with trade if it existed. (Remember that the interbank market freezes if and only if an equilibrium with trade cannot be sustained in the first place.) It follows that condition \( R_t < R \) is neither necessary nor sufficient for the interbank market to freeze. Hence Proposition 3.

**Proposition 3 (Interbank loan market freeze)** The interbank loan market freezes if and only if \( a_t > \bar{a}_t \equiv f_k^{-1}((\bar{R} + \delta - 1)/\bar{z}_t) \Leftrightarrow z_t < \bar{z}_t \equiv (\bar{R} + \delta - 1)/f_k(a_t) \).

The threshold \( \bar{a}_t \) is the maximum quantity of assets that the banking sector can allocate efficiently, that is, without the storage technology being used. Above this threshold counter–party fears are so prevalent that no trade takes place in the interbank market. In the rest of the paper we will refer to \( \bar{a}_t \) as banks’ absorption capacity. It increases with the level of TFP \( (\partial z_t/\partial z_t > 0) \) because following an increase in TFP the equilibrium corporate loan rate goes up and banks’ opportunity cost of diversion rises, which alleviates the moral hazard
problem. Symmetrically, there is a threshold $\zeta_t$ for the level of TFP below which the interbank market freezes; and this threshold increases with banks’ assets ($\partial \zeta_t / \partial a_t > 0$). Proposition 3 thus suggests that market freezes result either from the endogenous over–accumulation of assets by the household (when, given $z_t$, $a_t$ rises beyond $\bar{a}_t$), or from an exogenous adverse productivity shock that reduces banks’ absorption capacity (when, given $a_t$, $z_t$ falls below $\zeta_t$), as Figure 3 illustrates; or from a combination of both endogenous and exogenous factors. This variety of banking crises is a novel feature that will have important consequences for the macroeconomic dynamics. To see this, we report in Figure 4 a stylized representation of the household’s optimal asset accumulation rules for three different levels of $z_t$ (low, average, and high).
Given $z_t$, the optimal saving rule is discontinuous at $a_t = \bar{a}_t$. The upper branch (with $a_t \leq \bar{a}_t$) corresponds to normal times, where the interbank market functions well and all available assets in the economy are used to finance the firm. The lower branch (with $a_t > \bar{a}_t$) corresponds to crisis times. During a crisis, banks reduce their supply of loans to the firm, the firm reduces its demand for labor and the wage drops. The household dis-saves so as to sustain her consumption; hence the discontinuity in the decision rule when $a_t = \bar{a}_t$. To illustrate the variety of banking crises in the model, we focus on two polar examples of crises: $S$ and $U$ (it will become clear later that crises in the model are in effect “in–between” these two polar cases). The crisis in $S$ arises exogenously. Starting from the average steady state $O$, the economy experiences an exogenous large negative technology shock, which brings the economy down to $S$. Because this shock instantaneously reduces banks’ absorption capacity below the current level of assets, the crisis breaks out on impact. This crisis is purely driven by the bad shock and the amplification mechanism that the shock triggers. This is the channel usually depicted in the literature. The crisis in $U$ is of a very different nature, as it arises endogenously. Starting from the average steady state $O$, the economy experiences an unusually long sequence of positive TFP shocks, which leads the household to accumulate assets above banks’ absorption capacity. Points $S$ and $U$ provide useful — albeit extreme — examples of “exogenous” and “endogenous” crises. More generally, we will say — in light of the above — that a crisis arises endogenously whenever it is (i) preceded by an unusually high level of assets — or credit — and (ii) not associated with an unusually low level of TFP at the time it breaks out. Conversely, we will say that a crisis arises exogenously whenever it is (i) associated with an unusually low level of TFP at the time it breaks out and (ii) not preceded by an unusually high level of assets — or credit. Even though crises may follow credit booms, notice that not all credit booms ultimately lead to crises in our model. In other words, credit booms can be used as early warnings, but may also potentially generate many false alarms. Another predictor of crises in the model is the probability that a crisis breaks out in the next period, as derived in Proposition 4.

**Proposition 4 (Crisis probability)** Given the state of the economy $(z_t, a_t)$ at the end of period $t$, the probability that a banking crisis breaks out in period $t+1$ (conditional on the economy not being already in a crisis) is $P(z_{t+1} < \tau_{t+1}|z_t, a_t; z_t \geq \tau_t) = \Phi (\log \tau_{t+1} - \rho z_t \log z_t)$, where $\Phi (\cdot)$ denotes the normal c.d.f. Given $z_t$, $P(z_{t+1} < \tau_{t+1}|z_t, a_t; z_t \geq \tau_t)$ increases with $a_t$.

---

In theory, this second type of crisis does not even require any (positive) shock. To emphasize this point we present in Section E.1 of the technical appendix a purely deterministic version of the model — i.e. with a constant level of TFP — and show (i) that the model can generate endogenous booms and bust cycles and (ii) that the length of those deterministic cycles varies with the severity of financial frictions (for example, the larger $\theta$, the higher the frequency of crises).
This probability is fully consistent with general equilibrium effects and agents’ rational expectations. Therefore it can be considered as the “true” crisis probability. It increases as the economy approaches its absorption capacity (i.e., as \( a_t \) increases toward \( \bar{a}_t \)), as in this case interest rates go down and the moral hazard problem worsens (see Figure 3). In Section 5.2 we use this probability to construct early warnings of banking crises, and discuss the prediction performance of these early warnings.

4 Quantitative Analysis

The aim of this section is to investigate the quantitative properties of the model. To bring our model closer to the workhorse macroeconomic model we extend it in two directions; we allow for endogenous labor supply decisions, and we introduce technological progress that is consistent with the observed long term productivity growth in advanced economies. These features are standard and do not change the qualitative properties of the model. The equations characterizing the general equilibrium of the economy are reported in Appendix C.

4.1 Calibration of the Model

Technology is represented by a constant–returns to scale Cobb–Douglas function, \( z_t F(K_t, h_t; \Psi_t) \equiv z_t K_t^\alpha (\Psi_t h_t)^{1-\alpha} \) with \( \alpha \in (0, 1) \), where the term \( \Psi_t \) captures technological progress, is exogenous, and grows at the constant gross rate \( \psi > 1 \) (i.e., \( \Psi_t = \Psi_0 \psi^t \), with \( \Psi_0 > 0 \)). In the sequel, lower(upper)–case letters will refer to variables that are (not) deflated for growth. The household is endowed with preferences over consumption, \( C_t \), and hours worked, \( h_t \), represented by a Greenwood et al. (1988) utility function,

\[
\mathbb{E}_t \sum_{\tau = 0}^{\infty} \beta^\tau \frac{1}{1-\sigma} \left( C_{t+\tau} - \vartheta \Psi_{t+\tau} h_{t+\tau}^{1+\upsilon} \right)^{1-\sigma}
\]

where \( \upsilon \geq 0 \) is the inverse Frish labor supply elasticity. \( \hat{\beta} \) denotes the discount factor in the economy not deflated for growth. The presence of the technological progress term in the utility function ensures the existence of a balanced growth path (for another application see for example Jaimovich and Rebelo (2009). As is well known, in this class of utility functions wealth does not affect labor supply decisions. We only chose this specification for a practical reason as it yields a closed form for the banking sector’s (de–trended) absorption capacity that greatly simplifies the numerical solution of the equilibrium,

\[
\pi_t = \Gamma z_t^{\frac{1+\upsilon}{1-\alpha}}, \text{ with } \Gamma \equiv \left( \frac{1-\alpha}{\upsilon} \right)^\frac{1}{\upsilon} \left( \frac{\alpha}{\vartheta (1+\upsilon)} \right)^{\frac{(1+\upsilon)}{\upsilon (1-\alpha)}}.
\]

The model is calibrated on a yearly basis to be consistent with the facts presented in Section 2. The calibration, reported in Table 3 is most standard. We set \( \hat{\beta} \) so that the household
discounts the future at a 3% rate per annum in the economy deflated for growth. We assume that the labor supply elasticity is 2, such that $\nu = 0.5$. The labor dis–utility parameter $\vartheta$ is such that the household would supply one unit of labor in a deterministic version of the model. The risk aversion parameter $\sigma$ is set to 4.5, which lies within the range of estimated values. The capital elasticity in the production function $\alpha$ is set to 0.3, and we assume that capital depreciates at a 10% rate per annum ($\delta = 0.1$). To calibrate the data generating process of TFP we proceed in three steps. First, we use the model to back out a time series for the logarithm of TFP that is consistent with Fernald (2012)'s annual series of output, capital and labor. We then fit a linear trend to this time series and obtain a long term annual growth rate of TFP of 1.2% ($\psi = 1.012$). Finally, we use the de–trended TFP series to estimate the AR(1) process in relation (3.1), and obtain $\rho_z = 0.9$ and $\sigma_z = 1.77%$. Given the importance of parameters $\sigma$, $\nu$, $\rho_z$ and $\sigma_z$ for the dynamics of our model, we will discuss the sensitivity of the model to changes in their values.

The remaining parameters pertain to the banking sector, and include the return on storage $\gamma$, the diversion technology parameter, $\theta$, and the distribution of banks $\mu(\cdot)$. For tractability reasons we assume that $\mu(p) = p^\lambda$, with $\lambda \in \mathbb{R}^+$. The parameters of the banking sector are calibrated jointly so that (i) the spread between the real corporate loan rate and the implicit real risk free rate equals 1.7%, (ii) the real corporate loan rate equals 4.4%, and (iii) a financial recession occurs on average every 42 years. For statistics (i) and (ii) we use the real lending rate on mid–size business loans for the US between 1990 and 2011, as reported in the US Federal Reserve Bank’s Survey of Terms of Business Lending, and the real Federal Fund rate. We obtain $\gamma = 0.94$, $\lambda = 25$, and $\theta = 0.093$. Based on this calibration, the model generates an average interbank loan rate of 0.90% and an implied threshold for the real corporate loan rate of 2.62% (i.e., $\bar{R} = 1.0262$).

Note that we do not calibrate the model to replicate a priori any of Facts #2 (financial recessions are deeper and longer) and #3 (financial recessions follow credit booms) precisely because we want to discuss later the ability of the model to replicate these facts. We solve the model numerically using a collocation method, allowing for discontinuities in the asset accumulation decision rule at the points where the economy switches regime, \( a_t = \bar{a}_t \).

4.2 The Economy in Normal Times

We analyze the response of the economy to a positive one standard deviation productivity shock. Figure 5 compares the dynamics in our model (thick plain line) with that in a frictionless model (dotted line), which is obtained by setting either \( \gamma = 0 \) (no moral hazard), \( \theta = 0 \) (no moral hazard), or \( \lambda = +\infty \) (all banks have \( p = 1 \)). This frictionless version of our model corresponds to a standard Real Business Cycle (RBC) model. The responses of output, hours worked, consumption, and investment are essentially the same in the two models. Our model only exhibits slightly more amplification than the RBC model due to a financial accelerator mechanism that tends to magnify the effects of the shock. In particular, following the shock the corporate loan rate rises, which relaxes banks’ borrowing constraints in the interbank market. As the aggregate demand for interbank loans increases, the equilibrium interbank loan rate goes up and inefficient banks switch from the demand to the supply side of the market, so that the moral hazard problem recedes; hence the financial accelerator. However, this accelerator mechanism is hardly noticeable. Importantly, the economy does not experience any banking crisis after the shock. Indeed, even though the corporate loan rate eventually falls below its steady state level as the household accumulates assets, at no

\[ a_t = \bar{a}_t \]

Details on the numerical solution method are provided in Section A of the appendix.

In all these cases savings are channeled to the most efficient bank \( p = 1 \), either as an equilibrium result or because \( p = 1 \) is the only type of bank in the economy.
point does it fall below $\overline{R}$ (not shown). We show in the companion technical appendix that the model also behaves like a standard financial accelerator model following a negative one standard deviation productivity shock. Banking crises in the model are indeed rare events that occur under specific conditions, as we show in the next section.

4.3 Typical Boom–Bust

This section describes the typical conditions under which banking crises, and hence financial recessions, occur in our model. As already discussed in Section 3.4, banking crises can be driven either by exogenous productivity shocks, or by the household’s asset accumulation behavior, or by both. Which factor typically leads to a banking crisis is a quantitative question, which we settle by simulating the calibrated version of the model. Starting from the average steady state we simulate the model over 500,000 periods, and identify the years when a crisis breaks out as well as the path of the main aggregates —in deviation from their trend— 40 years before and 20 years after each crisis. We then compute, for each variable, the median of the distribution of paths, and refer to this median path as the “typical path”. The left panel of Figure 6 describes the endogenous dynamics of banks’ assets as well as banks’ absorption capacity along this typical path, and the right panel describes the exogenous dynamics of TFP and of its innovations. By convention, period 0 corresponds to the period when the crisis breaks out.

Figure 6: Typical path to crisis (deviations from trend) (I)

The first important result that emerges from Figure 6 is that the typical banking crisis is not due to an unusually large, exogenous, negative shock. There is a negative TFP innovation in the year of the crisis (right panel, squared markers); but it is a $1.44 - \sigma_z$ shock, which is neither unusual nor statistically different from zero at the 5% threshold. Following this shock, TFP and banks’ absorption capacity fall to 2.8% and 11.5% below trend, respectively. Such levels...
are reached 18.5% of the time in the simulations, and therefore are not unusual either. This suggests that the exogenous dynamics of TFP alone is not enough to generate rare financial recessions. The left panel shows in contrast that banks’ assets are disproportionately large at the time the crisis hits; they are 25% above their average steady state and 68% above the steady state associated with the current TFP level. That banks’ assets grow so much oversee happens only 6.7% of the time in our simulations. Based on Proposition 3 it is clear that, had banks not been so large in the first place, the fall in their absorption capacity would not have triggered the crisis.

This prompts the question why the banking sector can grow so large. Since in our model banks’ assets are entirely financed by the household, banks’ expansion results from an excessive accumulation of savings or, as Bernanke (2005) coined it, from a saving glut. In a neoclassical framework like ours, where savings are driven by the household’s consumption smoothing behavior, a saving glut can only develop following an unusually and unexpectedly long string of positive TFP innovations, as the right panel of Figure 6 illustrates (square markers). To understand how things work it is useful to decompose the pre–crisis period into two phases. During the first phase, TFP raises above trend and stays above it for a long time (right panel, plain line). These productivity gains result from the sequence of positive TFP innovations, which are small but yet large enough to overcome the mean reverting dynamics of TFP. These are good times, where the economy is far from its absorption capacity, the moral hazard problem is benign, crises are unlikely (see middle right panel of Figure 7), and it is optimal for the household to accumulate savings. This first phase lasts long, which gives the household enough time to build–up an unusually large stock of assets. This is the phase during which the saving glut develops, and feeds a boom in credit (see Figure 7).

The second pre–crisis phase starts when TFP reverts back to its trend. As productivity gains peter out, the economy gets closer to its absorption capacity, output reverts to trend and the credit/output ratio rises. The equilibrium corporate and interbank loan rates both fall significantly below their average level; counter–party fears rise; and the crisis probability reaches 25% in the year before the crisis. The household’s asset accumulation process in the run–up to the crisis results from two countervailing forces. On the one hand, as the expected return on bank deposits diminishes, the household tends to save less. On the other hand, the household also realizes that a crisis is looming, and that she will face large income losses if it materializes. To hedge against such a bad outcome and smooth her consumption profile,

---

15 Another way to obtain a saving glut would be to consider a two–country model, where the banking sector would be more developed (i.e. would have a lower \( \theta \)) in one of the countries, and would attract the developing countries’ savings, as in for instance Caballero et al. (2008), Mendoza et al. (2009), and Boissay (2011).

16 It should be clear that, given the positive 1.2% slope of the underlying productivity growth trend, productivity also increases during this second phase, but at a slower pace than its trend; we illustrate this in Section D.3 of the companion technical appendix by reporting the typical path to crisis with the underlying TFP trend.
Figure 7: Typical path to crisis (deviations from trend) (II)

Dynamics in normal times, ---- Dynamics during a crisis, ----------- Dynamics of \( \pi_t \), ------ Average across simulations, shaded area 66% Confidence band around typical path.

Note: The size of the banking sector corresponds to the sum (as opposed to consolidation) of all banks’ assets and therefore includes interbank funding. Formally, we report \( a_t + (1 - \mu (\pi_t)) \phi_t a_t \).
she therefore tends to save more. All in all, the stock of assets goes down, but consumption smoothing slows down the pace of dis-accumulation. In effect, the household does not dis-save fast enough to avoid the crisis because she does not internalize that, by maintaining her savings high, she makes the crisis more likely; an externality that we dub “the saving glut externality”. (We discuss the effects of this externality next section.)

In this context of financial fragility, the $1.44-\sigma_z$ negative TFP shock in period 0 is enough to bring the banking sector down. As it breaks out, the crisis manifests itself by a sudden reversal of the economy, with the size of the banking sector falling by 25% and the credit to assets ratio falling by around 10%. The banking crisis ends a long period of economic expansion where output, investment, hours worked, and consumption were more than 10% above their respective trends (see Figure 7). During the crisis, all these aggregates return back to trend.

Finally, the confidence band around the typical path in Figure 6 indicates that TFP is not always below trend in the year that precedes the crisis. In fact, the distribution of TFP in that year is not any different from its unconditional (symmetric) distribution. In contrast, the credit/output ratio is significantly above its long term average: it is more than 5% (10%) above its average steady state in the year that precedes the crisis in 95% (60%) of the cases. These results confirm the critical role of credit booms as an endogenous source of financial instability, and suggest that credit is more informative than TFP about the likelihood of a crisis. We will discuss this latter point in more detail in Section 5.2.

4.4 Inspecting the Mechanisms

There is nothing systematic about the prevalence of credit boom driven crises. This is a result, which can be partly explained by the asymmetric effects of the household’s consumption smoothing behavior on financial stability. In bad times TFP is relatively low and the household dis-saves, which by lowering the TFP threshold $z_t$ makes crises less likely (remember that $\partial z_t/\partial a_t > 0$). Hence, in bad times the dynamics of asset accumulation tends to stabilize the banking sector. In contrast, in good times TFP is relatively high and the household accumulates assets, which by raising $z_t$ makes crises more likely. In this case the dynamics of savings tends to destabilize the financial sector. As already discussed, though, asset accumulation by the household would not be as destabilizing if the household internalized its adverse effects on financial stability. Therefore we would argue that another important reason why most crises follow credit booms in the model is the presence of the saving glut externality. To shed more light on those mechanisms, we compare in Figure 8 the typical paths of assets and TFP in our baseline economy with the typical paths in an economy without the saving glut externality.

17 The interested reader is referred to Section D.7 of the companion technical appendix for details about the following discussion on distributions of TFP and the credit/output ratio before a crisis.
externality and in an economy with a constant saving rate. The idea here is that if both the externality or consumption smoothing are necessary to generate crises endogenously, then we would expect the typical crisis in those two economies to be generated exogenously, that is: (i) to be associated with an unusually low level of TFP at the time it breaks out and (ii) not to be preceded by an unusually high level of assets—or credit.

Figure 8: Typical paths to crisis without smoothing or externality (deviations from trend)

The first result that emerges from Figure 8 is that in the constant saving rate version of the model (circle markers) the typical banking crisis is not due to an endogenous boom in credit. As the crisis breaks out bank assets are hardly above their average steady state whereas TFP is significantly —6%— below trend, which happens only 4.9% of the time in the simulations; TFP shocks can thus almost entirely explain on their own why financial recessions are rare. Hence we would argue that consumption smoothing is an important ingredient to generate endogenous banking crises. But again, it is not sufficient. The typical path of TFP in the economy without the saving glut externality (right panel, diamond markers) indeed shows that in this economy too the crisis occurs when the level of TFP is relatively low. The reason is that the household, who now internalizes the adverse effects of her savings, not only saves overall less but also hastily dis-saves as soon as the likelihood of a crisis increases—precisely to avoid that the crisis materializes. To trigger the crisis the negative TFP shocks must therefore surprise the household, and be relatively large; here TFP must fall 4.3% below trend. We conclude that both the consumption smoothing behavior and the saving glut externality are necessary to generate banking crises endogenously in the calibrated version of the model. Consumption smoothing is important because it causes the development of the

---

18 The economy without the saving glut externality corresponds to an hypothetical economy in which the household internalizes—all else equal—the adverse effects of her savings decisions. In the case of the constant saving rate economy, the saving rate is set at the average steady state saving rate of the baseline economy (i.e., at $s = 0.24$). We describe the constant saving rate version of the model in Section C of the companion technical appendix, and explain how we solve the model in the absence of the saving glut externality in Section B.2 of the companion technical appendix.
saving glut in the first pre-crisis phase and creates the conditions under which even small shocks matter; the saving glut externality is equally important because it is what prevents the saving glut from resorbing when the economy is on the brink of a crisis.

5 Quantitative Implications

5.1 Financial Recession Statistics

This section assesses the ability of our model to account for the stylized facts on financial recessions, as documented in Section 2.19 We simulate a 500,000 period time series for output and identify all business cycle peaks and troughs so that the model generates the same percentage of recessions as in the data. A recession is then said to be a financial recession when a banking crisis breaks out between the peak that precedes it and the trough that ends it; we find that all banking crises in the simulations are associated with a recession.

Note: Δp,t,x (resp. Δp,p+2,x, Δp−2,p,x) denotes the percentage change of variable x from peak to trough (resp. from peak to peak+2 years, and peak-2 years to peak), where x denotes either output (y) or the Hodrick Prescott (λ = 6.25) cyclical component of credit (k^{HP}). Statistics based on a 500,000 time period simulation.

For comparison purposes, Table 4 reports the same statistics as Table 1. By construction, the model generates financial recessions with a frequency of 2.35% (Fact #1). These recessions feature a 12.6% drop in output from peak to trough and last on average 2.08 years. This is more than in other recessions, which are about 8 months shorter and where output falls by about half as much (4.98%). These differences are of the same order of magnitude as in the actual data. The model replicates Fact #2 that financial recessions are deeper and last longer than other recessions. However, the magnitude of the average financial recession

19In Section 4.2 we showed that financial frictions in our model hardly matter in normal times, which implies that our model has essentially the same business cycle properties (second order moments) as the textbook RBC model; see Section D.9 of companion technical appendix.
is almost twice as large as in the data: in the Schularik and Taylor (2012) data set output falls on average by 6.84% from peak to trough. Three features of the model contribute to these excessively large output losses. First, financial recessions are accompanied by a severe credit crunch, with credit falling by 9.44% from peak to trough (this is more than twice as much as what is observed in the data). Second, the firm is assumed to refinance its capital through bank loans only, and to roll over those loans every period; it does not retain earnings, and does not issue bonds or outside equity. As a consequence, capital is not pre–determined (only the household’s stock of assets is) and the fall in credit implies an equally large fall in capital. Finally, the absence of wealth effects, and therefore of leisure smoothing behavior, makes hours more responsive to fluctuations in wages. As capital falls, labor productivity and labor demand tank, wages go down, and the household reduces her supply of labor, which amplifies the initial fall in output. Hence the severe recession. In Section E.5 of the companion technical appendix, we show that a version of the model with a labor Frisch elasticity of 0.5 (instead of 2) would perform better regarding the dynamics of output, but not as well regarding the dynamics of credit.

Figure 9: Dynamics of output and credit gaps around recessions

(a) Financial Recessions

(b) Normal Recessions

Note: Average dynamics of the Hodrick-Prescott ($\lambda = 6.25$) cyclical component of (log) output and credit 6 periods before and after the start of a business cycle (period 0) with and without a banking crisis. For the sake of consistency, we treat the simulated series of output and credit as we treat the actual data in Figure 1.

The last two rows of Table 4 show statistics on the evolution of credit before the start of financial recessions. Credit grows by 3.7% in the two years that precede financial recessions.
(against 4.56% in the data), whereas it does not grow at all before other types of recessions (as in the data). Moreover, at the time the financial recession starts, credit is 3.81% above its Hodrick–Prescott trend, whereas it is basically on its trend in the case of other recessions. As a way to illustrate these results, we report in Figure 9 the dynamics of output and credit gaps around normal and financial recessions, both in the model and in the data. The figure indicates not only that financial recessions in the model are associated with a boom–bust cycle in credit — whereas normal recessions are not, but also that the dynamics observed in the data lie within the 66% confidence band of the model. The model is therefore consistent with Fact #3 that (only) financial recessions follow credit booms.

5.2 Crisis Prediction

The probability of falling into a crisis (see Proposition 4) can be used to construct early warnings in the context of our model; but it is not observable in the real world. Our aim in this section is to look into whether this model probability can be backed out from variables that are directly observable in the data, to construct early warnings based on this crisis probability, and to discuss the properties of those early warnings (Type–I and Type–II errors).

In the model three variables are key to understand the dynamics to crises: the level of bank deposit (or credit), TFP, and the credit/output ratio. (Instead of the credit/output ratio, one could consider the corporate loan rate, since given our production function the latter is a simple transformation of the former.) We simulate the model over 500,000 time periods, and then regress the one period ahead crisis probability at period \( t \) on these variables at period \( t \).

The results are reported in Table 5. We start by including the levels of credit \( a \) and TFP

Note: Regressions (1)-(4): linear regression using a logistic transformation of the period \( t \) model probability that a crisis breaks out in \( t + 1 \) as the dependent variable. Regression (5): logit regression using a dummy equal to one when a crisis breaks out in \( t + 1 \) (and zero otherwise) as dependent variable. All models include period \( t \) independent variables (in logarithm) and are conditional upon not being in a crisis in period \( t \). The regression sample includes 468,769 observations and 11,739 crises. Type–I: probability that the model fails to issue a warning. Type–II: probability that the model mistakenly issues a warning. A warning is issued as soon as the —model or fitted— crisis probability is above 12.75%, which threshold is chosen so that the type–II error is less than 5% in the case of model based warnings (first column).
(z) separately and find—as expected—that the fit is relatively poor. TFP, for example, is significant but explains only 3% of the variations in the crisis probability (regression (1)). The R$^2$ is higher in the regression with credit (regression (2)), which reflects the endogenous feature of the crises in the model. But it is still relatively low compared to the regressions with both credit and TFP. Indeed, with those credit supply and demand factors together the R$^2$ goes up to 69% (regression (3)); this result is robust to using the credit/output ratio (regression (4)). Next, we construct early warnings of crises based on the crisis probabilities. By convention, we issue a warning whenever the—model or fitted—probability of a crisis is above 12.75%. This cut-off value is chosen so that the warnings derived from the model probability (our benchmark) are statistically correct at the 5% threshold (i.e. so that the Type–II error is less than 5%). In this case, the model issues almost three times as many warnings as there are crises in the simulations (30,215 warnings for 11,739 crises; see Tables 4 and 5), but signals two thirds of the crises (the percentage of Type–I errors is 31.43%). Among the regression–based warnings, only those derived from the regression with the credit/output ratio (regression (4)) perform as well, with Type–I and Type–II errors of 36.79% and 4.92%, respectively. One caveat of regression (4), though, is that the dependent variable—the model probability of a crisis—is not observable and has no clear counterpart in the data. So, as a last experiment, we check whether the credit/output ratio remains a good predictor when we instead use as dependent variable a crisis dummy equal to one when a crisis breaks out in period t (and to zero otherwise), and estimate a Logit regression (regression (5)). In this case, to be consistent, we regress the crisis dummy on the one period lagged credit/output ratio. We find that the warnings derived from this regression have the same properties as those derived from the model probability. Altogether, these findings therefore suggest that it is reasonable to look at the credit/output ratio to predict crises.

5.3 Sensitivity Analysis

We begin our discussion by evaluating the sensitivity of our results to the key structural parameters of the model. In each case, we simulate the model over 500,000 periods, identify financial recessions, and compare their frequency, average duration, and average magnitude against the baseline in Table 4. The results are reported in Table 6.

We first make the household more willing to smooth consumption over time by raising the utility curvature parameter $\sigma$ from 4.5 (baseline) to 10. Following positive TFP shocks, the saving glut grows faster and larger than in the baseline model, leaving banks more exposed to adverse shocks. As a result, the probability of a financial recession is higher than in the baseline (4.74% versus 2.35%). The average financial recession is however somewhat shorter (1.75 periods) and milder (-10.61%). We next increase labor supply elasticity from 2 (baseline) to 4 ($\nu = 0.25$), thus making the household’s labor supply and income more
pro–cyclical. As a consequence the household accumulates assets faster and the frequency of financial recessions rises to 3.45%. The impact of the credit crunch on output is also magnified by the larger response of hours worked; ultimately, recessions are thus more severe and last longer.

</table>

Note: The alternative TFP model (last column) is a model where the TFP process is re–estimated correcting for the US productivity slowdown of the 70s. In this case, we use ρz = 0.7, σz = 0.015, and re–calibrate ψ to remove long term growth (ψ = 1), as well as γ, to have the same crisis probability as in the baseline (2.3%).

These first two experiments essentially affect the usual consumption smoothing mechanism. We now assess the sensitivity of our results to the specification of the banking sector. The fourth column of Table 6 shows the effect of an increase in productivity of banks’ diversion technology, as captured by a rise in θ from 0.1 (baseline) to 0.15. This aggravates the moral hazard problem between banks, reduces the absorption capacity of the economy (through its effect on the value of \( R \)), and increases the probability of a financial recession, which jumps from 2.35% to 5.87%; the recession is milder and shorter than in the baseline. A change in the distribution of banks has qualitatively similar effects. In the fifth column we consider an economy where \( λ = 20 \), instead of \( λ = 25 \) in the baseline, meaning that there are more inefficient banks in the economy. Since those banks have more incentives to divert cash, the moral hazard problem is more stringent and counter–party fears increase. Lenders impose a lower market funding ratio, aggregate demand and the interbank rate drop, the average quality of borrowers deteriorates. As a result, the frequency of financial recessions increases to 5.73%.

Next, we investigate the role of uncertainty. We start by raising \( σ_z \) from 0.0177 to 0.025, leaving \( ρ_z \) unchanged. The consequences are straightforward: the household accumulates more assets for consumption smoothing motives, the corporate loan rate decreases with respect to baseline, and the financial sector is more fragile. We then decrease the persistence of the shock down to \( ρ_z = 0.7 \) (instead of \( ρ_z = 0.9 \) in the baseline), leaving \( σ_z \) unchanged. This change exerts two opposite effects on financial stability. On the one hand, savings tend to be more sensitive to shocks and the household accumulates assets faster than in the baseline. On the other hand, periods of high total factor productivity levels are shorter, which implies that the household does not have as much time to accumulate assets. In our calibration, the first effect dominates, and financial recessions are more frequent, last longer and are more
protracted. Finally, we re-estimate the TFP shock process while detrending the logarithm of TFP with a linear trend break to fit the US productivity slowdown of the seventies. We find that the technology shock is less persistent (ρz = 0.7) and less volatile (σz = 0.015). Since our model is not designed to accommodate a break in the TFP growth trend we omit growth and set ψ = 1. For comparison purposes, we also adjust the return of storage (γ) so that financial recessions remain as frequent as in our benchmark economy. We find that financial recessions in this model are marginally milder and last as long as in the baseline.

6 Welfare Cost of Financial Frictions and Policy Intervention

The aim of this section is to evaluate and decompose the welfare cost of financial frictions —and thereby of the existence of financial recessions. Following Lucas (1987), we measure these welfare costs as the permanent percentage increase in consumption that would be necessary to make the household indifferent between the decentralized equilibrium allocation and the First Best allocation, which would prevail in a frictionless world (here, the RBC model). The results are reported in Table 7. We find that, all in all, financial frictions reduce consumption permanently by 2.20% (first column). These welfare losses can be decomposed into two parts. Some of these losses are due to the presence of externalities, that is, the saving glut externality and a “rebate” externality due to the household not internalizing that the aggregate cost of financial intermediation (cχt) is rebated. We measure the cumulated welfare cost of these externalities as the difference in welfare between the constrained efficient allocation and the decentralized equilibrium allocation. The constrained efficient allocation is defined as the allocation that a central planner would implement if she faced the same constraints as banks. We find that the externalities cost the household 0.61% of permanent consumption, which is large compared to what is usually found in the literature; Bianchi and Mendoza (2010) and Bianchi (2011), for example, report values ranging from 0.05% to 0.2%. However, these welfare losses are still of second order relative to those due to financial markets being deficient in the first place. Indeed, we also compute the welfare cost of the market and institutional deficiencies that are responsible for limited contract enforceability (moral

Note: The welfare associated to an allocation j is measured by \( W_j(c^j, h^j) = \sum_{t=0}^{\infty} \beta^t U(c_t^j, h_t^j) \) where \( c^j \equiv \{c_t^j\}_{t=0}^{\infty} \) and \( h^j \equiv \{h_t^j\}_{t=0}^{\infty} \). The table reports the permanent percentage difference consumption \( \omega \) between two allocations j and i that solves \( W_i((1+\omega)c_i', h_i') = W_j(c^j, h^j) \); allocation j is preferred to allocation i if \( \omega > 0 \). The welfare cost is computed based on 10,000 Monte–Carlo simulations of the model. FBA: First Best Allocation; DEA: Decentralized Equilibrium Allocation; CEA: Constrained Efficient Allocation; NIM: Equilibrium allocation in a model without interbank market.
hazard) and the lack of transparency (asymmetric information). We measure this cost as the difference of welfare between the First Best allocation and the constrained efficient allocation. We find that deficient institutions cost the household 1.53% of permanent consumption, i.e., more than twice as much as the externalities. Finally, for the sake of completeness, we calculate the welfare loss if interbank loans were not be permitted. To do so we compare our baseline economy with an hypothetical, financially under-developed economy with no interbank market. As Mendoza et al. (2007), we find that financial under-development has a sizeable, detrimental effect on welfare; it reduces permanent consumption by 4.61%.

The relatively large welfare cost of financial frictions calls for policy intervention. One set of policies are macro-prudential policies that make private agents internalize the effects of their decisions on financial stability. In this respect, the saving glut externality and the rebate externality have very different implications. As we discussed in Section 4.4, the saving glut externality essentially kicks in when a crisis is imminent or, more precisely, when following a marginal increase in deposits the crisis probability becomes strictly positive. In this case, the household indeed keeps too much assets in order to hedge against the fall in consumption she will face if the crisis materializes (see Figure 7), and —by doing so— inadvertently precipitates the crisis. Since a crisis induces an instantaneous fall in welfare, the optimal policy consists in giving the household an incentive to dis-save fast, to avoid the crisis. In contrast, the rebate externality always affects welfare, be a crisis imminent or not. If the household internalized that the cost of financial intermediation is rebated to her, then she would understand that the return on assets is more than \( r_t \), and therefore accumulate more assets. (In normal times, for instance, the relevant return on assets is \( R_t \), and not \( r_t \); see Appendix C.) All in all, the household thus accumulates too little assets when the economy is far away from a crisis and too much assets when it is close to it, in comparison with a constrained efficient central planner. Accordingly, a welfare improving policy would consist in subsidizing the marginal unit of deposit (or credit) when the probability of crisis is null and the banking sector can safely absorb it, and in taxing deposits —or reducing the subsidy— when a crisis is looming. Of course, the profile and timing of such a policy are critical. In the run up to a crisis, notably, taxes should not be raised too early, so as to let the economy reap the most benefits from high productivity; but they should not be raised too late, to give the household enough time to dis-save and keep assets below banks’ absorption capacity. That the welfare cost of externalities is low relative to that of institutions being deficient (see Table 7) however suggests that even an optimal macro-prudential policy would have rather limited effects on welfare. Structural reforms aiming at improving financial contract enforceability and transparency in the banking sector may potentially have a much bigger impact.

Notice that this policy implication heavily relies on our assumption that there is no deadweight loss in the economy. If the intermediation costs were not rebated, then there would be no under-accumulation of assets in normal times, and therefore no need to subsidize deposits (or credit).
7 Concluding Remarks

We offered a simple quantitative macro–economic model where endogenous financial developments could turn the real business cycle round. The model features a non–trivial banking sector, in which banks are heterogeneous with respect to their intermediation skills. This heterogeneity gives rise to an interbank market. Moral hazard and asymmetric information in this market lead to infrequent market meltdowns, banking crises, credit crunches and, ultimately, severe recessions. Our model has the potential to generate a variety of banking crises, and we view it as a step toward understanding the interactions between financial and real business cycles. In this respect, the quantitative properties of the model are encouraging.

For tractability reasons we made some strong assumptions and presented a stylized model, whose narrative of banking crises may not be taken at face value. Indeed, we left out some aspects of the banking sector that would deserve more attention in future extensions. For instance, we assumed that the household cannot finance the firm directly and —by the same token— that the firm cannot issue bonds or equity. A proper investigation of the interactions between financial and real business cycles must take into account the substitution effects that exist between direct and intermediated finance (see De Fiore and Uhlig, 2013). To keep matters simple we modeled a closed economy. Accordingly, the saving glut, which is key to the dynamics in our model, can only be fed by the domestic household. Opening the economy could have interesting insights as the saving glut would become global, thus offering the possibility to study how banking crises spread internationally. Finally, we ignored that frictions may exist between the banks and the household. Therefore, we could not pin down banks’ optimal funding structure, which in turn prevented us from studying the dynamics of bank leverage. It would be interesting to model bank leverage explicitly so as to get richer dynamics, and be in a position to discuss the effects of macro–prudential policies like changes in bank capital requirements. This and other extensions are left to future research.

A Solution Method

The decentralised equilibrium is solved using a collocation method. Solving the equilibrium boils down to finding the optimal decision rule $a_{t+1}(a_t; z_t) = G(a_t; z_t)$ for all possible values of $a_t$ and $z_t$.

We first construct a discrete representation of the distribution of the technology shock using the approach proposed by Tauchen and Hussey (1991). This yields a Markov chain representation of the technology shock with $z_t \in \{z_1, \ldots, z_{n_z}\}$ and a transition matrix $\Pi = (\pi_{ij})_{i,j=1}^{n_z}$ where $\pi_{ij} = P(z_{t+1} = z_j | z_t = z_i)$. We use $n_z = 15$, and look for $n_z$ decision rules $G(a_t; z_t)$, for $i = 1, \ldots, n_z$. Since the economy can be in two regimes—normal and crisis times—and we know when it reaches one regime or the other (see Proposition 3), we approximate the decision rules as

\[ G(a_t; z_t) \equiv \exp \left( \sum_{j=0}^{q} \xi_j^a(z_t) T_j(\phi(a_t)) \right) \mathbb{I}_{a_t \leq \pi_t} + \exp \left( \sum_{j=0}^{q} \xi_j^a(z_t) T_j(\phi(a_t)) \right) \mathbb{I}_{a_t > \pi_t}, \]

where $z_t$ denotes a particular level of the total factor productivity in the grid and $\pi_t = \pi(z_t)$ is the corresponding absorption capacity (see Section 4.1). $T_j(\cdot)$ is a Chebychev polynomial of order $j$, $\xi_j^a(z_t)$ (resp. $\xi_j^c(z_t)$) is the coefficient associated to this polynomial when the economy is in normal times (resp. in a banking crisis) for the productivity level $z_t$. $\phi(a_t)$ is a function that maps the level of assets into interval $(-1, 1)$. Finally $\mathbb{I}_{a_t \leq \pi_t}$ (resp. $\mathbb{I}_{a_t > \pi_t}$) is an indicator function which takes value one in normal (resp. crisis) times and 0 otherwise. The optimal decision rule $a_{t+1}(a_t; z_t)$ is given by the fixed point solution to the Euler equation.

Our resolution algorithm proceeds as follows.

1. Choose a domain $[a_m, a_s]$ of approximation for $a_t$. We consider values that guarantee that the conditional steady state associated with each level of the technology shock can be reached. This led us to use $a_m = 0.5$ and $a_s = 8$.

2. Choose an order of approximation $q$, compute the $q + 1$ roots of the Chebychev polynomial of order $q + 1$ as

\[ \zeta_k = \cos \left( \frac{(2k - 1)\pi}{2(q + 1)} \right) \text{ for } k = 1, \ldots, q + 1 \]

and formulate initial guesses $\xi_j^{(0)}(z_t)$ and $\xi_j^{(0)}(z_t)$ for the coefficients of the Chebychev polynomial, for $i = 1, \ldots, n_z$ and $j = 1, \ldots, q$. We chose $q = 15$ so as to obtain an accurate approximation of the decision rule.

3. Define the (reciprocal of the) mapping function $\phi(a_t)$, and compute $a_k$ (for $k = 1, \ldots, q + 1$) as

\[ a_k = \phi^{-1}(\zeta_k) \equiv \begin{cases} \exp \left( \log(a_m) + (\zeta_k + 1) \frac{\log(\pi_t) - \log(a_m)}{2} \right) & \text{for normal times} \\ \exp \left( \log(\pi_t) + (\zeta_k + 1) \frac{\log(a_s) - \log(\pi_t)}{2} \right) & \text{for crisis times} \end{cases} \]

for $k = 1, \ldots, q + 1$. Note that the grid of values for $a$ depends fundamentally on the level of the technology shock as the threshold $\pi_t$ depends on the level of productivity $z_t$ (see Section 4.1):

\[ \pi_t = \Gamma z_t \frac{1+\nu}{\nu(1+\gamma)}, \text{ with } \Gamma \equiv \left( 1 - \frac{\alpha}{\theta} \right)^{\frac{1}{\nu}} \left( \frac{\alpha}{\bar{R} + \delta - 1} \right)^{\frac{\nu+\gamma}{\nu(1+\gamma)}}. \]
4. Using the $n$th iteration on coefficients $\xi_j^{(n)}(z_i)$ and $\xi_j^{c(n)}(z_i)$, compute for each level of $a_k$ (with $k = 1, \ldots, q + 1$) the values of the decision rule:

$$G^{(n)}(a_k; z_i) \equiv \exp \left( \sum_{j=0}^{q} \xi_j^{(n)}(z_i) T_j(\zeta_k) \right) I_{a_k < \pi_i} + \exp \left( \sum_{j=0}^{q} \xi_j^{c(n)}(z_i) T_j(\zeta_k) \right) I_{a_k > \pi_i}$$

as well as the control variables, in particular hours worked, $h_i^{(n)}(a_k, z_i)$ and household’s income, $e_i^{(n)}(a_k, z_i) \equiv y_i^{(n)}(a_k, z_i) + (1 - \delta) a_k$.

5. Use the decision rule $G^{(n)}(a_k; z_i)$ to compute period $t + 2$’s level of assets $a_{i+2}^{(n)}(a_k; z_i, z_t) = G^{(n)}(G^{(n)}(a_k; z_i), z_t)$ as well as period $t+1$’s hours worked $h_{t+1}^{(n)}(a_k; z_i, z_t)$, income $e_{t+1}^{(n)}(a_k; z_i, z_t)$, and interest rate $r_{t+1}^{(n)}(a_k; z_i, z_t)$, for all $k = 1, \ldots, q + 1, i = 1, \ldots, n_z$, and $\ell = 1, \ldots, n_z$.

6. Using the Euler equation (see equation 3 in appendix C) and the budget constraint $e^{(n)}(a_k; z_i) = e_t(a_k; z_i) - \psi a_{t+1}^{(n)}(a_k; z_i)$, compute

$$a_{t+1}^{(n+1)}(a_k; z_i) \equiv \frac{1}{\psi} \left( e_{t}^{(n)}(a_k; z_i) - \omega \frac{h_t^{(n)}(a_k; z_i, z_t)}{1 + \nu} - \left( \beta \sum_{\ell=1}^{n_z} \pi_{\ell} r_{t+1}^{(n)}(a_k; z_i, z_{\ell}) \left( e_{t+1}^{(n)}(a_k; z_i, z_{\ell}) \right) - \psi a_{t+1}^{(n)}(a_k; z_i, z_{\ell}) - \delta \right) \right)$$

for each value of $k$ (with $k = 1, \ldots, q + 1$) and each value of $i$ (with $i = 1, \ldots, n_z$).

7. Project $e^{(n+1)}_{t+1}(a_k; z_i)$ on the Chebychev polynomials $T_j(\zeta_k)$ to obtain estimates $\hat{\xi}_j^{(n)}(z_i)$ and $\hat{\xi}_j^{c(n)}(z_i)$. If the distance between $(\hat{\xi}_j^{(n)}(z_i), \hat{\xi}_j^{c(n)}(z_i))$ and $(\xi_j^{(n)}(z_i), \xi_j^{c(n)}(z_i))$ is close enough to zero in the sense that the norm of the difference is less than $\varepsilon \equiv 1e-6$, then stop. Otherwise, update the coefficients as

$$\begin{align*}
\hat{\xi}_j^{(n+1)}(z_i) &= (1 - \omega) \xi_j^{(n)}(z_i) + \omega \hat{\xi}_j^{(n)}(z_i) \\
\hat{\xi}_j^{c(n+1)}(z_i) &= (1 - \omega) \xi_j^{c(n)}(z_i) + \omega \hat{\xi}_j^{c(n)}(z_i)
\end{align*}$$

where $\omega \in (0, 1)$ sets the speed at which we update the decision rule, and go back to step 4.

8. Once convergence is achieved, check that the residuals of the Euler equation are close enough to zero, in the sense that the intertemporal error an agent would make by using the approximation is small enough (See Judd, 1992).

B Proofs of Propositions

**Proposition 1** The program of a borrowing bank writes

$$\max_{\phi_t} pR_t(1 + \phi_t) - \rho_t \phi_t$$

s.t. $pR_t(1 + \phi_t) - \rho_t \phi_t \geq \rho_t$

$$\gamma(1 + \theta \phi_t) \leq \rho_t$$

The participation constraint indicates that only banks with ability $p \geq p_t \equiv p_t/R_t$ will borrow. We focus on this segment of the market. The problem simplifies to

$$\max_{\phi_t} pR_t(1 + \phi_t) - \rho_t \phi_t$$

s.t. $\gamma(1 + \theta \phi_t) \leq \rho_t$
for \( p \geq \bar{p}_t \). Let us denote by \( \xi \) the Lagrange multiplier associated to the incentive constraint, the first order conditions are then

\[
pR_t - \rho_t = \gamma \theta \xi
\]
\[
\xi (p_t - \gamma (1 + \phi_t)) = 0
\]

The result follows from \( \xi \) being strictly positive for all \( p > \bar{p}_t \).

**Proposition 4**: The market clearing condition (8a) in normal times together with the optimal demand for capital yields the normal times equilibrium corporate loan rate \( R_t = z_t f_k(a_t) + 1 - \delta \). The interbank market freezes if and only if this rate is below \( \bar{R} \), i.e., if and only if \( z_t f_k(a_t) < \bar{R} + \delta - 1 \), which can be restated either as \( a_t \geq \bar{a}_t \equiv f_k^{-1}(\bar{R} + \delta - 1)/z_t \) or \( z_t \leq \bar{z}_t \equiv (\bar{R} + \delta - 1)/f_k(a_t) \).

**Proposition 4**: At the end of period \( t \), the probability that a crisis breaks out in \( t + 1 \) is the probability that \( R_{t+1} \) falls below \( \bar{R} \), conditional on state \( (z_t, a_t) \) and on the economy not being already in a crisis \((z_t \geq \bar{z}_t)\), i.e., \( \mathbb{P}(R_{t+1} < \bar{R} | z_t, a_t; z_t \geq \bar{z}_t) \). The definition of the probability follows from the firm’s first order condition and the definition of \( \bar{z}_{t+1} \). Notice that

\[
\mathbb{P}(z_{t+1} < \bar{z}_{t+1} | z_t, a_t; z_t \geq \bar{z}_t) = \mathbb{P}
\left( z_{t+1} < \bar{R} < \frac{\bar{R} + \delta - 1}{f_k(a_{t+1})} | z_t, a_t; z_t \geq \bar{z}_t \right)
\]

where \( a_{t+1} \) is given by the household’s optimal decision rule and is a function of \( a_t \) and \( z_t \). Since \( f(. \) is concave and \( a_{t+1} \) increases monotonically with \( a_t \) for all \( z_t \geq \bar{z}_t \), it is easy to see that the crisis probability monotonically increases with \( a_t \), and therefore (given \( z_t \)), with \( a_t/\bar{a}_t \).

**C Equations of the Model with endogenous Labour Supply**

1. \( y_t = z_t k_t^\alpha h_t^{1-\alpha} + (\gamma + \delta - 1) (a_t - k_t) \)
2. \( R_t = a k_t^{\alpha/(1-\alpha)} \frac{\bar{z}_t^{1+\alpha}}{z_t} (1 - \alpha) \frac{1-\alpha}{\bar{z}_t} + 1 - \delta \)
3. \( c_t - \phi \frac{h_t^{1+\upsilon}}{1+\upsilon} = \beta E_t \left[ (c_{t+1} - \phi \frac{h_{t+1}^{1+\upsilon}}{1+\upsilon})^{-\sigma} r_{t+1} \right] \)
4. \( h_t = \left( \frac{1-\alpha}{\bar{z}_t} \frac{1+\upsilon}{\upsilon+\alpha} \right)^{\frac{1}{\upsilon+\alpha}} k_t^{\frac{1+\upsilon}{\upsilon+\alpha}} \)
5. \( \bar{a}_t \equiv (1 - \alpha) / \bar{\phi} \left( \alpha / (\bar{R} + \delta - 1) \right)^{\frac{\upsilon+\alpha}{\upsilon+\alpha}} \bar{z}_t^{\frac{1+\upsilon}{\upsilon+\alpha}} \)
6. \( i_t = \psi a_{t+1} - (1 - \delta) a_t \)
7. \( y_t = a_t + i_t \)
8. \( \chi_t = (R_t - r_t) a_t - (R_t - \gamma) (a_t - k_t) \)

If \( a_t \leq \bar{a}_t \) (normal times)

9a. \( k_t = a_t \)
10a. \( \frac{r_t}{R_t} = \int_{\bar{p}_t}^{1} p \frac{d\mu(p)}{1 - \mu(\bar{p}_t)} \)
11a. \( \bar{a}_t = \frac{\partial t}{R_t} \)
12a. \( R_t = \frac{\rho_t}{\mu^{-1}(\frac{\rho_t - \gamma}{\rho_t - (1-\delta)\gamma})}, \) with \( \rho_t > \bar{p} \)
If $a_t > \bar{a}_t$ (crisis times)

9b. $k_t = a_t - \mu (\gamma/R_t) a_t$

10b. $\frac{r_t}{R_t} = \frac{\gamma}{R_t} \mu (\gamma/R_t) + \int_{\gamma/R_t}^{1} p \, d\mu (p)$

11b. $p_t = \gamma/R_t$

12b. $\rho_t = \gamma$

Few comments are in order here. (i) During a crisis assets $a_t - k_t$ are stored for return $\gamma$. Since capital depreciates at rate $\delta$, the value added of storage is $\gamma + \delta - 1$, as reflected in equation 1. (Remember that $\gamma + \delta - 1 > 0$.) (ii) The good market clearing conditions (7) is derived from Walras’ law and the agents’ budget constraints. Summing up the household and the firm’s budget constraints (1) and (3), one gets:

$c_t + \psi a_{t+1} = z_t k_t^{\alpha} a_t^{1-\alpha} + (1 - \delta) k_t + r_t a_t - R_t k_t + \chi_t$, which simplifies to $c_t + i_t = y_t - (\gamma + \delta - 1)(a_t - k_t) + (1 - \delta) (k_t - a_t) + r_t a_t - R_t k_t + \chi_t \iff y_t + \chi_t = c_t + i_t + (R_t - r_t) a_t - (R_t - \gamma) (a_t - k_t)$. It can be checked that $\chi_t = \int_{\gamma/R_t}^{1} (1 - p) \, (1 + \phi_t) R_t a_t \, d\mu (p)$, and that the resource identity reduces to $y_t = c_t + i_t$. In crisis times, by definition one has $\chi_t = \int_{\gamma/R_t}^{1} (1 - p) \, R_t a_t \, d\mu (p)$, which simplifies to (using 9b and 10b):

$\chi_t = (1 - \mu (\gamma/R_t)) R_t a_t - \int_{\gamma/R_t}^{1} p \, R_t \, a_t \, d\mu (p) = R_t k_t - r_t a_t + \gamma (k_t - a_t) = (R_t - r_t) a_t - (R_t - \gamma) (a_t - k_t)$. In normal times, by definition one has $\chi_t = \int_{\gamma/R_t}^{1} (1 - p) \, (1 + \phi_t) R_t a_t \, d\mu (p)$, which simplifies to (using 9a and 10a and the fact that in equilibrium $1 + \phi_t = 1/(1 - \mu (\bar{a}_t)))$: $\chi_t = (R_t - r_t) a_t$.  

41
